### Course 236299

# **Project segment 1: Text classification**

In this project segment you will build several varieties of text classifiers using PyTorch.

- 1. A majority baseline.
- 2. A naive Bayes classifier.
- 3. A logistic regression (single-layer perceptron) classifier.
- 4. A multilayer perceptron classifier.

You'll use these to classify air travel queries from a standard dataset, and compare the results.

# Preparation {-}

```

```

cuda

print(device)

# The task: Answer types for ATIS queries

device = torch.device("cuda" if torch.cuda.is\_available() else

"cpu")

For this and future project segments, you will be working with a standard natural-language-processing dataset, the ATIS (Airline Travel Information System) dataset. This dataset is composed of queries about flights – their dates, times, locations, airlines, and the like.

The ATIS dataset was generated using a "Wizard of Oz" methodology, a common approach in early NLP research and human-computer interaction more generally. Subjects were asked to interact with a "prototype of a voice-input information retrieval system. It has the same information that is contained in the Official Airline Guide (OAG) to help you make air travel plans." In reality, behind the curtain, two confederates were transcribing the queries and providing the answers. In this way, an "ecologically realistic" set of queries was obtained.

Over the years, the dataset has been annotated in all kinds of ways, with parts of speech, informational chunks, parse trees, and even corresponding SQL database queries. You'll use various of these annotations in future assignments. For this project segment, however, you'll pursue an easier classification task: **given a query, predict the answer type**.

These queries ask for different types of answers, such as

- Flight IDs: "Show me the flights from Washington to Boston"
- Fares: "How much is the cheapest flight to Milwaukee"
- City names: "Where does flight 100 fly to?"

In all, there are some 30 answer types to the queries.

Below is an example taken from this dataset:

```
Query:
```

show me the afternoon flights from washington to boston

SQL:

```
SELECT DISTINCT flight_1.flight_id FROM flight flight_1 ,
airport_service airport_service_1 , city city_1 ,
airport_service airport_service_2 , city city_2
   WHERE flight_1.departure_time BETWEEN 1200 AND 1800
   AND ( flight_1.from_airport =
airport_service_1.airport_code
        AND airport_service_1.city_code = city_1.city_code
        AND city_1.city_name = 'WASHINGTON'
        AND flight_1.to_airport =
airport_service_2.airport_code
        AND airport_service_2.city_code = city_2.city_code
        AND city_2.city_name = 'BOSTON' )
```

In this project segment, we will consider the answer type for a natural-language query to be the target field of the corresponding SQL query. For the above example, the answer type would be *flight\_id*.

# Loading and preprocessing the data

Read over this section, executing the cells, and **making sure you** understand what's going on before proceeding to the next parts.

First, let's download the dataset.

```
In [70]: data_dir = "https://raw.githubusercontent.com/nlp-236299/data/master/ATIS/"
    os.makedirs('data', exist_ok=True)
    for split in ['train', 'dev', 'test']:
        wget.download(f"{data_dir}/{split}.nl", out='data/')
        wget.download(f"{data_dir}/{split}.sql", out='data/')
```

Next, we process the dataset by extracting answer types from SQL queries and saving in CSV format.

```
In [71]:
        def get_label_from_query(query):
             """Returns the answer type from `query` by dead reckoning.
             It's basically the second or third token in the SQL query.
             match = re.match(r'\s*SELECT\s+(DISTINCT\s*)?(\w+\.)?(?P<label>\w+)', query)
             if match:
                 label = match.group('label')
             else:
                 raise RuntimeError(f'no label in query {query}')
             return label
         for split in ['train', 'dev', 'test']:
             sql_file = f'data/{split}.sql'
             nl_file = f'data/{split}.nl'
             out_file = f'data/{split}.csv'
             with open(nl_file) as f_nl:
                 with open(sql_file) as f_sql:
                     with open(out_file, 'w') as fout:
                         writer = csv.writer(fout)
                         writer.writerow(('label','text'))
                         for text, sql in zip(f_nl, f_sql):
                              text = text.strip()
                              sql = sql.strip()
                              label = get_label_from_query(sql)
                              writer.writerow((label, text))
```

Let's take a look at what each data file looks like.

```
In [72]: shell('head "data/train.csv"')
```

label, text

flight\_id,list all the flights that arrive at general mitchell international from various cities

flight\_id,give me the flights leaving denver august ninth coming back to boston flight id,what flights from tacoma to orlando on saturday

fare\_id,what is the most expensive one way fare from boston to atlanta on america
n airlines

flight\_id, what flights return from denver to philadelphia on a saturday

flight\_id,can you list all flights from chicago to milwaukee

flight\_id, show me the flights from denver that go to pittsburgh and then atlanta flight\_id,i'd like to see flights from baltimore to atlanta that arrive before no on and i'd like to see flights from denver to atlanta that arrive before noon flight\_id, do you have an 819 flight from denver to san francisco

It's a CSV file with the answer type in the first column and the query text in the second.

We use datasets to prepare the data, as in lab 1-5. More information on datasets can be found at https://huggingface.co/docs/datasets/loading.

Generating train split: 0 examples [00:00, ? examples/s]

          })
         We build a tokenizer from the training data to tokenize text and convert tokens into
         word ids.
In [76]:
         MIN FREQ = 3 # words appearing fewer than 3 times are treated as 'unknown'
         unk_token = '[UNK]'
         pad_token = '[PAD]'
         tokenizer = Tokenizer(WordLevel(unk token=unk token))
         tokenizer.pre_tokenizer = Whitespace()
         tokenizer.normalizer = normalizers.Lowercase()
         trainer = WordLevelTrainer(min_frequency=MIN_FREQ, special_tokens=[pad_token, un
         tokenizer.train from iterator(train data['text'], trainer=trainer)
         We use datasets.Dataset.map to convert text into word ids. As shown in lab 1-5, first
         we need to wrap tokenizer with the transformers.PreTrainedTokenizerFast
         class to be compatible with the datasets library.
In [77]: hf_tokenizer = PreTrainedTokenizerFast(tokenizer_object=tokenizer,
                                                  pad_token=pad_token,
                                                  unk_token=unk_token)
In [78]: def encode(example):
              return hf_tokenizer(example['text'])
         train_data = train_data.map(encode)
```

We also need to convert label strings into label ids.

```
# Add a new column `label_id`
In [79]:
         train_data = train_data.add_column('label_id', train_data['label'])
         val_data = val_data.add_column('label_id', val_data['label'])
         test_data = test_data.add_column('label_id', test_data['label'])
         # Convert feature `label_id` from strings to integer ids
         train_data = train_data.class_encode_column('label_id')
         # Use the label vocabulary on training data to convert val and test sets
         label2id = train_data.features['label_id']._str2int
         val data = val data.class encode column('label id')
         val_data = val_data.align_labels_with_mapping(label2id, "label_id")
         test_data = test_data.class_encode_column('label_id')
         test_data = test_data.align_labels_with_mapping(label2id, "label_id")
        Casting to class labels:
                                   0% l
                                                | 0/4379 [00:00<?, ? examples/s]
                                   0%|
                                                | 0/491 [00:00<?, ? examples/s]
        Casting to class labels:
                                           | 0/491 [00:00<?, ? examples/s]
        Aligning the labels: 0%
                                               | 0/448 [00:00<?, ? examples/s]
        Casting to class labels:
                                   0%|
        Aligning the labels:
                                            | 0/448 [00:00<?, ? examples/s]
In [80]: # Compute size of vocabulary
         text_vocab = tokenizer.get_vocab()
         label_vocab = train_data.features['label_id']._str2int
         vocab_size = len(text_vocab)
         num_labels = len(label_vocab)
         print(f"Size of vocab: {vocab size}")
         print(f"Number of labels: {num_labels}")
        Size of vocab: 514
        Number of labels: 30
```

To get a sense of the kinds of things that are asked about in this dataset, here is the list of all of the answer types in the training data, along with their label IDs.

```
In [81]: for label in label_vocab:
    print(f"{label_vocab[label]:2d} {label}")
```

### Handling unknown words

Note that we mapped words appearing fewer than 3 times to a special *unknown* token (we're using <code>[UNK]</code> ). We do this for two reasons:

- 1. Due to the scarcity of such rare words in training data, we might not be able to learn generalizable conclusions about them.
- 2. Introducing an unknown token allows us to deal with out-of-vocabulary words in the test data as well: we just map those words to <code>[UNK]</code> .

```
In [82]: print (f"Unknown token: {unk_token}")
    unk_index = text_vocab[unk_token]
    print (f"Unknown token id: {unk_index}")

# UNK example
    example_unk_token = 'IAmAnUnknownWordForSure'
    print (f"An unknown token: {example_unk_token}")
    print (f"Mapped back to word id: {hf_tokenizer(example_unk_token).input_ids}")
    print (f"Mapped to [UNK]'s?: {all([id == unk_index for id in hf_tokenizer(exampl
    Unknown token: [UNK]
    Unknown token id: 1
    An unknown token: IAmAnUnknownWordForSure
    Mapped back to word id: [1]
    Mapped to [UNK]'s?: True
```

To facilitate batching sentences of different lengths into the same tensor as we'll see later, we also reserved a special padding symbol [PAD].

```
In [83]: print (f"Padding token: {pad_token}")
    pad_index = text_vocab[pad_token]
    print (f"Padding token id: {pad_index}")

Padding token: [PAD]
    Padding token id: 0
```

### Batching the data

To load data in batches, we use torch.utils.data.DataLoader. This enables us to iterate over the dataset under a given BATCH\_SIZE which specifies how many examples we want to process at a time.

```
In [84]: BATCH_SIZE = 32
         # Defines how to batch a list of examples together
         def collate_fn(examples):
             batch = \{\}
             bsz = len(examples)
             label_ids = []
             for example in examples:
                 label ids.append(example['label id'])
             label_batch = torch.LongTensor(label_ids).to(device)
             input_ids = []
             for example in examples:
                 input_ids.append(example['input_ids'])
             max_length = max([len(word_ids) for word_ids in input_ids])
             text_batch = torch.zeros(bsz, max_length).long().fill_(pad_index).to(device)
             for b in range(bsz):
                 text_batch[b][:len(input_ids[b])] = torch.LongTensor(input_ids[b]).to(de
             batch['label_ids'] = label_batch
             batch['input_ids'] = text_batch
             return batch
         train_iter = torch.utils.data.DataLoader(train_data, batch_size=BATCH_SIZE, coll
         val_iter = torch.utils.data.DataLoader(val_data, batch_size=BATCH_SIZE, coll
         test_iter = torch.utils.data.DataLoader(test_data, batch_size=BATCH_SIZE, coll
```

Let's look at a single batch from one of these iterators.

```
In [85]: batch = next(iter(train_iter))
    text = batch['input_ids']
    print (f"Size of text batch: {text.size()}")
    print (f"Third sentence in batch: {text[2]}")
    print (f"Mapped back to string: {hf_tokenizer.decode(text[2])}")
    print (f"Mapped back to string skipping padding: {hf_tokenizer.decode(text[2]), s

    label = batch['label_ids']
    label_vocab_itos = train_data.features['label_id']._int2str # map from label ids
    print (f"Size of label batch: {label.size()}")
    print (f"Third label in batch: {label[2]}")
    print (f"Mapped back to string: {label_vocab_itos[label[2].item()]}")
```

Mapped back to string: what flights from tacoma to orlando on saturday [PAD] [PAD]

Mapped back to string skipping padding: what flights from tacoma to orlando on sa turday

```
Size of label batch: torch.Size([32])
Third label in batch: 15
Mapped back to string: flight_id
```

You might notice some padding tokens [PAD] when we convert word ids back to strings, or equivalently, padding ids 0 in the corresponding tensor. The reason why we need such padding is because the sentences in a batch might be of different lengths, and to save them in a 2D tensor for parallel processing, sentences that are shorter than the longest sentence in the batch need to be padded with some placeholder values. Later during training you'll need to make sure that the paddings do not affect the final results.

Alternatively, we can also directly iterate over the individual examples in train\_data, val\_data and test\_data. Here the returned values are the raw sentences and labels instead of their corresponding ids, and you might need to explicitly deal with the unknown words, unlike using bucket iterators which automatically map unknown words to an unknown word id.

```
In [86]: for _, example in zip(range(5), train_data):
    print(f"{example['label']:10} -- {example['text']}")

flight_id -- list all the flights that arrive at general mitchell international
    from various cities
    flight_id -- give me the flights leaving denver august ninth coming back to bost
    on
     flight_id -- what flights from tacoma to orlando on saturday
    fare_id -- what is the most expensive one way fare from boston to atlanta on a
    merican airlines
    flight_id -- what flights return from denver to philadelphia on a saturday
```

#### **Notations used**

In this project segment, we'll use the following notations.

- Sequences of elements (vectors and the like) are written with angle brackets and commas  $(\langle w_1, \dots, w_M \rangle)$  or directly with no punctuation  $(w_1 \cdots w_M)$ .
- Sets are notated similarly but with braces,  $(\{v_1, \ldots, v_V\})$ .
- Maximum indices (M, N, V, T, and X in the following) are written as uppercase italics.
- Variables over sequences and sets are written in boldface (**w**), typically with the same letter as the variables over their elements.

In particular,

- $\mathbf{w} = w_1 \cdots w_M$ : A text to be classified, each element  $w_i$  being a word token.
- $\mathbf{v} = \{v_1, \dots, v_V\}$ : A vocabulary, each element  $v_k$  being a word type.
- $\mathbf{x} = \langle x_1, \dots, x_X \rangle$ : Input features to a model.
- $\mathbf{y} = \{y_1, \dots, y_N\}$ : The output classes of a model, each element  $y_i$  being a class label.
- $\mathbf{T} = \langle \mathbf{w}^{(1)}, \dots, \mathbf{w}^{(T)} \rangle$ : The training corpus of texts.
- $\mathbf{Y} = \langle y^{(1)}, \dots, y^{(T)} \rangle$ : The corresponding gold labels for the training examples in T.

# To Do: Establish a majority baseline

A simple baseline for classification tasks is to always predict the most common class. Given a training set of texts  $\mathbf T$  labeled by classes  $\mathbf Y$ , we classify an input text  $\mathbf w=w_1\cdots w_M$  as the class  $y_i$  that occurs most frequently in the training data, that is, specified by

```
\argmax_i \sharp (y_i)
```

and thus ignoring the input x entirely (!).

#### Implement the majority baseline and compute test accuracy using the starter code

**below.** For this baseline, and for the naive Bayes classifier later, we don't need to use the validation set since we don't tune any hyper-parameters.

```
In [87]: def majority_baseline_accuracy(train_data, test_data):
    label_counts = Counter(train_data['label'])
    most_common_label = label_counts.most_common(1)[0][0]

    correct = sum(1 for label in test_data['label'] if label == most_common_labe accuracy = correct / len(test_data['label'])

    return most_common_label, accuracy
```

How well does your classifier work? Let's see:

```
In [88]: # Call the method to establish a baseline
    most_common_label, test_accuracy = majority_baseline_accuracy(train_data, test_d
    # For comparison, evaluate it on the training data as well
    _, train_accuracy = majority_baseline_accuracy(train_data, train_data)

print(f'Most common label: {most_common_label}\n'
    f'Test accuracy: {test_accuracy:.3f}\n'
    f'Train accuracy: {train_accuracy:.3f}')
```

Most common label: flight\_id
Test accuracy: 0.683
Train accuracy: 0.733

# To Do: Implement a Naive Bayes classifier

## Review of the naive Bayes method

Recall from lab 1-3 that the Naive Bayes classification method classifies a text  $\mathbf{w} = \langle w_1, w_2, \dots, w_M \rangle$  as the class  $y_i$  given by the following maximization:

$$rgmax \Pr(y_i \, | \, \mathbf{w}) pprox rgmax \Pr(y_i) \cdot \prod_{j=1}^M \Pr(w_j \, | \, y_i)$$

or equivalently (since taking the log is monotonic)

$$\operatorname*{argmax}_{i} \Pr(y_i \mid \mathbf{w}) = \operatorname*{argmax}_{i} \log \Pr(y_i \mid \mathbf{w}) \tag{1}$$

$$pprox rgmax \left( \log \Pr(y_i) + \sum_{j=1}^M \log \Pr(w_j \, | \, y_i) 
ight)$$

All we need, then, to apply the Naive Bayes classification method is values for the various log probabilities: the priors  $\log \Pr(y_i)$  and the likelihoods  $\log \Pr(w_j \mid y_i)$ , for each feature (word)  $w_j$  and each class  $y_i$ .

We can estimate the prior probabilities  $\Pr(y_i)$  by examining the empirical probability in the training set. That is, we estimate

$$\Pr(y_i) pprox rac{\sharp(y_i)}{\sum_j \sharp(y_j)}$$

We can estimate the likelihood probabilities  $\Pr(w_j | y_i)$  similarly by examining the empirical probability in the training set. That is, we estimate

$$ext{Pr}(w_j \,|\, y_i) pprox rac{\sharp(w_j, y_i)}{\sum_{j'}\sharp(w_{j'}, y_i)}$$

To allow for cases in which the count  $\sharp(w_j, y_i)$  is zero, we can use a modified estimate incorporating add- $\delta$  smoothing:

$$\Pr(w_j \, | \, y_i) pprox rac{\sharp(w_j, y_i) + \delta}{\sum_{j'} \sharp(w_{j'}, y_i) + \delta \cdot V}$$

# Two conceptions of the naive Bayes method implementation

We can store all of these parameters in different ways, leading to two different implementation conceptions. We review two conceptions of implementing the naive Bayes classification of a text  $\mathbf{w} = \langle w_1, w_2, \dots, w_M \rangle$ , corresponding to using different representations of the input  $\mathbf{x}$  to the model: the index representation and the bag-of-words representation.

Within each conception, the parameters of the model will be stored in one or more matrices. The conception dictates what operations will be performed with these matrices.

#### Using the index representation

In the first conception, we take the input elements  $\mathbf{x}=\langle x_1,x_2,\ldots,x_M\rangle$  to be the *vocabulary indices* of the words  $\mathbf{w}=w_1\cdots w_M$ . That is, each word token  $w_i$  is of the word type in the vocabulary  $\mathbf{v}$  at index  $x_i$ , so

$$v_{x_i}=w_i$$

In this representation, the input vector has the same length as the word sequence.

We think of the likelihood probabilities as forming a matrix, call it  $\mathbf{L}$ , where the i, j-th element stores  $\log \Pr(v_j \mid y_i)$ .

$$\mathbf{L}_{ij} = \log \Pr(v_i | y_i)$$

Similarly, for the priors, we'll have

$$\mathbf{P}_i = \log \Pr(y_i)$$

Now the maximization can be implemented as

$$\operatorname*{argmax}_{i} \log \Pr(y_i) + \sum_{j=1}^{M} \log \Pr(w_j \, | \, y_i) = \operatorname*{argmax}_{i} \mathbf{P}_i + \sum_{j=1}^{M} \mathbf{L}_{i,x_j} \tag{3}$$

Implemented in this way, we see that the use of each input  $x_i$  is as an *index* into the likelihood matrix.

#### Using the bag-of-words representation

Notice that since each word in the input is treated separately, the order of the words doesn't matter. Rather, all that matters is how frequently each word type occurs in a text. Consequently, we can use the bag-of-words representation introduced in lab 1-1.

Recall that the bag-of-words representation of a text is just its frequency distribution over the vocabulary, which we will notate  $bow(\mathbf{w})$ . Given a vocabulary of word types  $\mathbf{v}=\langle v_1,v_2,\ldots,v_V\rangle$ , the representation of a sentence  $\mathbf{w}=\langle w_1,w_2,\ldots,w_M\rangle$  is a vector  $\mathbf{x}$  of size V, where

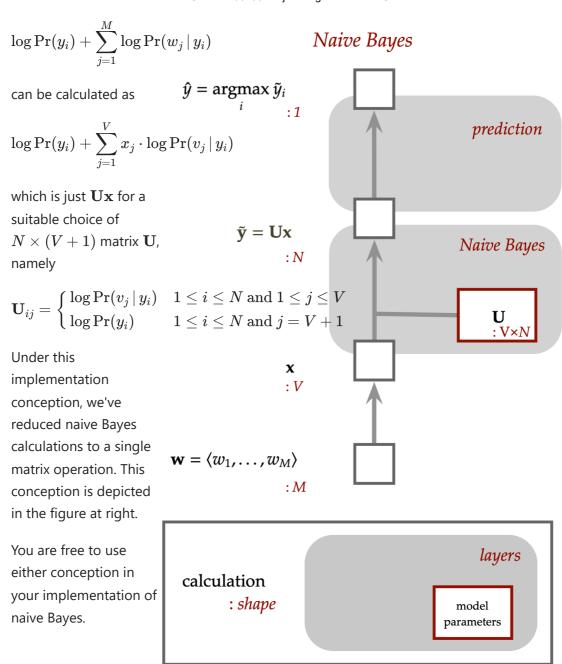

$$bow(\mathbf{w})_j = \sum_{i=1}^M \mathbb{1}[w_i = v_j] \qquad ext{for } 1 \leq j \leq V$$

We write  $1[w_i=v_j]$  to indicate 1 if  $w_i=v_j$  and 0 otherwise. For convenience, we'll add an extra (V+1)-st element to the end of the bag-of-words vector, a single 1 whose use will be clear shortly. That is,

$$bow(\mathbf{w})_{V\perp 1} = 1$$

Under this conception, then, we'll take the input  $\mathbf{x}$  to be  $bow(\mathbf{w})$ . Instead of the input having the same length as the text, it has the same length as the vocabulary.

As described in lecture, represented in this way, the quantity to be maximized in the naive Bayes method

## Implement the naive Bayes classifier

For the implementation, we ask you to implement a Python class NaiveBayes that will have (at least) the following three methods:

- \_\_init\_\_ : An initializer that takes text\_vocab , label\_vocab , and pad\_index as inputs.
- 2. train: A method that takes a training data iterator and estimates all of the log probabilities  $\log \Pr(y_i)$  and  $\log \Pr(v_i \mid y_i)$  as described above. Perform add- $\delta$

- smoothing with  $\delta=1$ . These parameters will be used by the evaluate method to evaluate a test dataset for accuracy, so you'll want to store them in some data structures in objects of the class.
- 3. evaluate: A method that takes a test data iterator and evaluates the accuracy of the trained model on the test set.

You can organize your code using either of the conceptions of Naive Bayes described above.

You should expect to achieve about an 86% test accuracy on the ATIS task.

```
In [92]: class NaiveBayes():
             def __init__ (self, text_vocab, label_vocab, pad_index):
                 self.pad_index = pad_index
                 self.V = len(text_vocab) # vocabulary size
                 self.N = len(label_vocab) # the number of classes
                 self.priors = None
                 self.likelihoods = None
             def train(self, iterator):
                 """Calculates and stores log probabilities for training dataset `iterato
                 label_counts = Counter()
                 word_label_counts = Counter()
                 total labels = 0
                 for batch in iterator:
                     labels = batch['label_ids']
                     inputs = batch['input_ids']
                     for i, label in enumerate(labels):
                         label counts[label.item()] += 1
                         total_labels += 1
                         for token in inputs[i]:
                             if token.item() != self.pad_index:
                                  word_label_counts[(token.item(), label.item())] += 1
                 self.priors = {
                     label: count / total labels for label, count in label counts.items()
                 self.likelihoods = {}
                 for (word, label), count in word label counts.items():
                     self.likelihoods[(word, label)] = (count + 1) / (
                          label counts[label] + self.V
                     )
             def evaluate(self, iterator):
                 """Returns the model's accuracy on a given dataset `iterator`."""
                 correct = 0
                 total = 0
                 for batch in iterator:
                     labels = batch['label ids']
                     inputs = batch['input_ids']
                     for i, label in enumerate(labels):
                         scores = {
```

Training accuracy: 0.817
Test accuracy: 0.777

# To Do: Implement a logistic regression classifier

In this part, you'll complete a PyTorch implementation of a logistic regression (equivalently, a single layer perceptron) classifier. We review logistic regression here highlighting the similarities to the matrix-multiplication conception of naive Bayes. Thus, we take the input  $\mathbf x$  to be the bag-of-words representation  $bow(\mathbf w)$ . But as before you are free to use either implementation approach.

# Review of logistic regression

Similar to naive Bayes, in logistic regression, we assign a probability to a text  $\mathbf x$  by merely multiplying an  $N \times V$  matrix  $\mathbf U$  by it. However, we don't stipulate that the values in the matrix  $\mathbf U$  be estimated from the training corpus in the "naive Bayes" manner. Instead, we allow them to take on any value, using a training regime to select good values.

In order to make sure that the output of the matrix multiplication  $\mathbf{U}\mathbf{x}$  is mapped onto a probability distribution, we apply a nonlinear function to renormalize the values. We use the softmax function, a generalization of the sigmoid function from lab 1-4, defined by

$$ext{softmax}(\mathbf{z})_i = rac{\exp(z_i)}{\sum_{j=1}^N \exp(z_j)}$$

for each of the indices i from 1 to N.

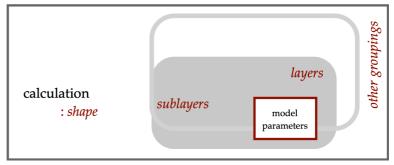

In summary, we model  $\Pr(y \mid \mathbf{x})$  as

$$\Pr(y_i \mid \mathbf{x}) = \operatorname{softmax}(\mathbf{U}\mathbf{x})_i$$

The calculation of  $\Pr(y \mid \mathbf{x})$  for each text  $\mathbf{x}$ is referred to as the forward computation. In summary, the forward computation for logistic regression involves a linear calculation (Ux) followed by a nonlinear calculation (softmax). We think of the perceptron (and more generally many of these neural network models) as transforming from one representation to another. A perceptron performs a linear transformation from the index or bag-of-words representation of the text to a representation as a vector, followed by a nonlinear transformation, a softmax or sigmoid, giving a representation as a probability distribution over the class labels. This single-

(single-layer perceptron)  $l = -\log(\mathbf{e}_y \cdot \tilde{\mathbf{y}})$  : 1  $\hat{\mathbf{y}} = \operatorname{argmax} \tilde{\mathbf{y}}_i$  : 1  $| \mathbf{v} = \operatorname{single layer} | \mathbf{v} = \operatorname{single la$ 

Logistic regression

involves two *sublayers*. (In the next part of the project segment, you'll experiment with a multilayer perceptron, with two perceptron layers, and hence four sublayers.)

The loss function you'll use is the negative log probability  $-\log \Pr(y \mid \mathbf{x})$ . The negative is used, since it is convention to minimize loss, whereas we want to maximize log likelihood.

The forward and loss computations are illustrated in the figure at right. In practice, for numerical stability reasons, PyTorch absorbs the softmax operation into the loss function nn.CrossEntropyLoss. That is, the input to the nn.CrossEntropyLoss function is

layer perceptron thus

the vector of sums  $\mathbf{U}\mathbf{x}$  (the last step in the box marked "your job" in the figure) rather than the vector of probabilities  $\Pr(y \mid \mathbf{x})$ . That makes things easier for you (!), since you're responsible only for the first sublayer.

Given a forward computation, the weights can then be adjusted by taking a step opposite to the gradient of the loss function. Adjusting the weights in this way is referred to as the *backward* computation. Fortunately, torch takes care of the backward computation for you, just as in lab 1-5.

The optimization process of performing the forward computation, calculating the loss, and performing the backward computation to improve the weights is done repeatedly until the process converges on a (hopefully) good set of weights. You'll find this optimization process in the <a href="train\_all">train\_all</a> method that we've provided. The trained weights can then be used to perform classification on a test set. See the <a href="evaluate">evaluate</a> method.

## Implement the logistic regression classifier

For the implementation, we ask you to implement a logistic regression classifier as a subclass of torch.nn.Module. You need to implement the following methods:

1. \_\_init\_\_ : an initializer that takes text\_vocab , label\_vocab , and pad\_index as inputs.

During initialization, you'll want to define a tensor of weights, wrapped in torch.nn.Parameter, initialized randomly, which plays the role of **U**. The elements of this tensor are the parameters of the torch.nn instance in the following special technical sense: It is the parameters of the module whose gradients will be calculated and whose values will be updated. Alternatively, **you might find it easier** to use the nn.Embedding module which is a wrapper to the weight tensor with a lookup implementation.

- 2. forward : given a text batch of size batch\_size X max\_length , return a tensor of logits of size batch\_size X num\_labels . That is, for each text x in the batch and each label y, you'll be calculating Ux as shown in the figure, returning a tensor of these values. Note that the softmax operation is absorbed into nn.CrossEntropyLoss so you won't need to deal with that.
- 3. train\_all: A method that performs training. You might find lab 1-5 useful.
- 4. evaluate: A method that takes a test data iterator and evaluates the accuracy of the trained model on the test set.

Some things to consider:

1. The parameters of the model, the weights, need to be initialized properly. We suggest initializing them to some small random values. See torch.uniform\_.

- 2. You'll want to make sure that padding tokens are handled properly. What should the weight be for the padding token?
- 3. In extracting the proper weights to sum up, based on the word types in a sentence, we are essentially doing a lookup operation. You might find nn.Embedding or torch.gather useful.

You should expect to achieve about **90%** accuracy on the ATIS classificiation task.

```
In [94]:
         class LogisticRegression(nn.Module):
           def __init__ (self, text_vocab, label_vocab, pad_index):
             super().__init__()
             self.pad_index = pad_index
             # Keep the vocabulary sizes available
             self.N = len(label_vocab) # num_classes
             self.V = len(text_vocab) # vocab_size
             # Specify cross-entropy loss for optimization
             self.criterion = nn.CrossEntropyLoss()
             # TODO: Create and initialize a tensor for the weights,
                     or create an nn. Embedding module and initialize
              # Matrice de poids (Ux), initialisée aléatoirement
             self.weights = nn.Embedding(self.V, self.N)
             nn.init.uniform_(self.weights.weight, -0.1, 0.1)
           def forward(self, text_batch):
             # TODO: Calculate the logits (Ux) for the `text_batch`,
                     returning a tensor of size batch_size x num_labels
                     # Obtenir les poids pour chaque mot dans le batch
             embeddings = self.weights(text_batch) # [batch_size x seq_len x num_labels]
                 # Somme sur la séquence pour obtenir [batch_size x num_labels]
             logits = embeddings.sum(dim=1) # Somme des vecteurs de chaque mot
             return logits
           def train all(self, train iter, val iter, epochs=8, learning rate=3e-3):
             # Use Adam to optimize the parameters
             optim = torch.optim.Adam(self.parameters(), lr=learning rate)
             best_validation_accuracy = -float('inf')
             best_model = None

# To Do: Implement a multilayer perceptron

# Review of multilayer perceptrons

In the last part, you implemented a perceptron, a model that involved a linear calculation (the sum of weights) followed by a nonlinear calculation (the softmax, which converts the summed weight values to probabilities). In a multi-layer perceptron, we take the output of the first perceptron to be the input of a second perceptron (and of course, we could continue on with a third or even more).

In this part, you'll implement the forward calculation of a twolayer perceptron, again letting PyTorch handle the backward calculation as well as the optimization of parameters. The first layer will involve a linear summation as before and a sigmoid as the nonlinear function. The second will involve a linear summation and a softmax (the latter absorbed, as before, into the loss function).

Thus, the difference from the logistic regression implementation is simply the adding of

the sigmoid and second linear calculations. See the figure for the structure of the computation.

## Implement a multilayer perceptron classifier

For the implementation, we ask you to implement a two layer perceptron classifier, again as a subclass of the torch.nn module. You might reuse quite a lot of the code from logistic regression. As before, you need to implement the following methods:

\_\_init\_\_\_: An initializer that takes text\_vocab, label\_vocab, pad\_index, and hidden\_size specifying the size of the hidden layer (e.g., in the above illustration, hidden\_size is D).

During initialization, you'll want to define two tensors of weights, which serve as the parameters of this model, one for each layer. You'll want to initialize them randomly.

The weights in the first layer are a kind of lookup (as in the previous part), mapping words to a vector of size hidden\_size. The nn.Embedding module is a good way to set up and make use of this weight tensor.

The weights in the second layer define a linear mapping from vectors of size hidden\_size to vectors of size num\_labels. The nn.Linear module or torch.mm for matrix multiplication may be helpful here.

2. forward : Given a text batch of size batch\_size X max\_length , the forward function returns a tensor of logits of size batch\_size X num\_labels .

That is, for each text  $\mathbf{x}$  in the batch and each label c, you'll be calculating  $MLP(bow(\mathbf{x}))$  as shown in the illustration above, returning a tensor of these values. Note that the softmax operation is absorbed into nn.CrossEntropyLoss so you don't need to worry about that.

For the sigmoid sublayer, you might find nn.Sigmoid useful.

- 3. train\_all: A method that performs training. You might find lab 1-5 useful.
- 4. evaluate: A method that takes a test data iterator and evaluates the accuracy of the trained model on the test set.

You should expect to achieve at least 90% accuracy on the ATIS classificiation task.

```
In [96]:
    class MultiLayerPerceptron(nn.Module):
        def __init__ (self, text_vocab, label_vocab, pad_index, hidden_size=128):
            super().__init__ ()
            self.pad_index = pad_index
            self.hidden_size = hidden_size
            # Keep the vocabulary sizes available
            self.N = len(label_vocab) # num_classes
            self.V = len(text_vocab) # vocab_size

# Specify cross-entropy loss for optimization
```

```

### Lessons learned

**Question:** Rank the methods as to their performance. What lessons do you learn from the ranking?

The best model based on our experiments was the Multilayer Perceptron. After it comes Logistic Regression and Naive Bayes comes last Multilayer Perceptron outperformed others due to its utilization of an advanced architecture in conjunction with non-linear activation functions which enables it to extract better features out of the inputs. The method is Linear Regression more basic and efficient when used for linearly separable datasets, but had limited scope in terms of more complicated relationships. Our observations show Naive Bayes as the least suitable model because it relies on oversimplified assumptions regarding the independence of words which works best for other than natural language data. Clearly we can see that advanced architectures with non-linearities and deep structures are more efficient than most of their simpler counterparts; it must be noted that this also translates into more computing power and longer training periods. In some simple cases or where only limited computing resources are available, ways like Logistic Regression or even Naive Bayes can function as expected.

**Question:** Take a look at some of the examples that were classified correctly and incorrectly by your best method. Do you notice anything about the incorrectly classified examples that might indicate *why* they were classified incorrectly?

From what has been outlined before, it seems that the model is deficient in context and has not been sufficiently exposed to uncommon data. In the majority of the instances, the model could not comprehend due to inadequate context. Increasing the dataset or adding more diverse alternatives can mend these issues. Uncommon or ambiguous data can be included while training the model, due to which a better association can be formed. Ambiguous wordings or even questions which are multi labeled can add to the training process, providing a more fulfilling data set. An expanded and reworked dataset can aid in enhancing accuracy while labeling the sentences

In [ ]: ...

# Prompting Modern Large Language Models (LLMs)

**Question:** Modern large-scale language models (such as Claude, ChatGPT, Gemini, Llama) have various capabilities, that can be shown by prompting them correctly (i.e. giving them a correct input prompt). For example, they can even be useful for solving text classification, discussed in this segment. Try to see if you can prompt an LLM (of your choosing) to solve the task of text classification on some of the examples of data seen in this segment. Write a short paragraph about your experience. Note that your not expected to devise a fool-proof prompting method, but only to qualitatively experiment with prompting.

I attempted to use a large language model like ChatGPT for the text classification problem by giving it prompts containing sample sentences and sample labels. The aim of the model was to estimate the labels during use for novel sentences. The model's performance was quite reasonable, especially if the examples provided during the prompt were lucid and varied. New task often floundered on somewhat ambiguous or rare phrases, a problem that mirrors the practice models that we tested. The experience made me appreciate how important the quality of the prompt is, as it contributes a lot to the performance of the LLM. This can be especially useful to LLM models, as being verbose on the task and providing sufficient examples increases its efficiency. What this means is that with good attention to prompt design, LLMs can be used productively for tasks such as text classification without having to be explicitly trained on the dataset.

## **Debrief**

**Question:** We're interested in any thoughts you have about this project segment so that we can improve it for later years, and to inform later segments for this year. Please list any issues that arose or comments you have to improve the project segment. Useful things to comment on include the following, but you are not restricted to these:

- Was the project segment clear or unclear? Which portions?
- Were the readings appropriate background for the project segment?
- Are there additions or changes you think would make the project segment better?

The project segment was clear overall, and the step-by-step instructions made it easy to follow. The readings provided sufficient background to understand the concepts and implement the methods. The practical coding tasks were well-designed and aligned with the theoretical parts, which helped reinforce the learning. To make it even better, more examples of how to handle edge cases or ambiguous data could be added, and a brief explanation of how to debug common issues might help future students. Overall, it was a well-structured and engaging project segment.

# Instructions for submission of the project segment

This project segment should be submitted to Gradescope, which will be made available some time before the due date.

Project segment notebooks are manually graded, not autograded using otter as labs are. (Otter is used within project segment notebooks to synchronize distribution and solution code however.) **We will not run your notebook before grading it.** Instead, we ask that you submit the already freshly run notebook. The best method is to "restart kernel and run all cells", allowing time for all cells to be run to completion. You should submit your code to Gradescope at the code submission assignment at

https://www.gradescope.com/courses/903849?submit\_assignment\_id=5229513.

We also request that you **submit a PDF of the freshly run notebook**. The simplest method is to use "Export notebook to PDF", which will render the notebook to PDF via LaTeX. If that doesn't work, the method that seems to be most reliable is to export the notebook as HTML (if you are using Jupyter Notebook, you can do so using File -> Print Preview), open the HTML in a browser, and print it to a file. Then make sure to add the file to your git commit. Please name the file the same name as this notebook, but with a .pdf extension. (Conveniently, the methods just described will use that name by default.) You can then perform a git commit and push and submit the commit to Gradescope at https://www.gradescope.com/courses/903849? submit\_assignment\_id=5229489.

# End of project segment 1 {-}
